- Appendix B Nitrogen loading analysis

EXECUTIVE SUMMARY

Introduction

This report provides a screening-level assessment of Massachusetts embayments at risk of eutrophication. It estimates the nitrogen loadings to the study embayments and their ability to eliminate nitrogen. For each embayment, nitrogen loading was estimated from non-point sources (*i.e.*, surface run-off, groundwater, and atmospheric deposition) and wastewater treatment plants using methodologies consistent with prior studies in Massachusetts coastal areas (*e.g.*, Buzzards Bay Project, Cape Cod Commission). Non-point source contributions of nitrogen were estimated using a land use analysis similar to Costa (1994) and Valiela *et al.* (in press). The report assesses embayment sensitivity using the Cape Cod Commission nitrogen sensitivity index (Eichner *et al.*, 1995). Nitrogen loading and nitrogen sensitivity estimates were combined to rank the eutrophication potential of the study embayments. Based on these results, the authors provide recommendations for future study and management of the embayments.

Methodology to estimate nitrogen loading

River estimates

To prevent gross overestimates of nitrogen loading, Massachusetts Bays Program (MBP) staff requested that delineations of river watersheds end at the first upstream dam or impoundment (in the case of the Merrimack River, the delineation ended at its tidally-influenced reach). In lieu of modeling the various loss mechanisms, nitrogen loads into the marine system were estimated using river flow and nitrogen concentration data. Data for these calculations were obtained from Menzie-Cura & Associates, Inc. (1991).

Land use estimates

To estimate non-point source loadings of nitrogen, a land use analysis was performed for each embayment watershed. The analysis combines watershed land use with nitrogen loading coefficients. Land use data was obtained from MassGIS, a GIS system developed and maintained by the Massachusetts Executive Office of Environmental Affairs (EOEA). Nitrogen loading coefficients were derived for each MassGIS land use category using conservative assumptions and data from various nitrogen studies. The loading coefficients account for various non-point sources of nitrogen, such as fertilizer application and septic systems, and losses that attenuate nitrogen concentrations, such as denitrification. To obtain non-point source nitrogen loadings, the land use areas within a watershed (ha) were multiplied by their respective nitrogen

loading coefficients ($\text{kg ha}^{-1} \text{ yr}^{-1}$). In addition, changes in land use and predicted future changes in nitrogen loadings were evaluated using the methodology of Costa (1994).

Atmospheric deposition estimates

Atmospheric nitrogen loads directly onto embayment surfaces were estimated using wet and dry depositional rates from Golomb *et al.* (1996).

Point source estimates

Effluent concentrations and flow were used to estimate nitrogen loadings from wastewater treatment plants (WWTPs). Data for these estimates were obtained directly from facilities, EPA National Pollutant Discharge Elimination System (NPDES) data, and Menzie-Cura & Associates, Inc. (1991). To ensure that nitrogen inputs were not double-counted, non-point source loading estimates (*i.e.*, those based on land use analysis) were corrected to reflect the percentage of homes that are publicly sewered.

Total loading estimates

To arrive at a total nitrogen loading for each embayment, the non-point and point source estimates described above were summed. Total nitrogen loadings were used as part of the evaluation process to rank embayments.

Ranking scheme

A ranking scheme was developed to evaluate the sensitivity of the study embayments to eutrophication. To rank nitrogen loadings, the loadings were normalized by embayment surface area ($\text{kg ha}^{-1} \text{ yr}^{-1}$). Jaworski (1981) suggested a “permissible” nitrogen loading of $54 \text{ kg ha}^{-1} \text{ yr}^{-1}$ to minimize eutrophication of shallow (4 to 9 meters) nitrogen limited estuarine zones. In addition, he provides estimates of loadings for estuaries of varying trophic condition. Loadings as high as $128 \text{ kg ha}^{-1} \text{ yr}^{-1}$ were reported for nitrogen limited estuaries that were non-eutrophic. The normalized nitrogen loadings of the study embayments were ranked using this range of values. Nitrogen loading rates limits have also been derived by the Buzzards Bay Project (BBP). However, these limits are based on flushing (expressed as $\text{mass volume}^{-1} \text{ time}^{-1}$) and therefore cannot be directly applied to this analysis.

To judge an embayment’s ability to eliminate nitrogen, the report uses the “nitrogen sensitivity index”, developed by the Cape Cod Commission (CCC) to prioritize Cape Cod watersheds (Eichner *et al.*, 1995). This scheme evaluates several morphological parameters, including the

ratio of the area of the embayment to ocean inlet width, the ratio of the area of the embayment to area of salt water wetlands, and shoreline development. The CCC scheme assigns a score to each parameter, based on a comparison to benchmark values. The nitrogen sensitivity index is calculated by adding the parameter scores. This report categorizes nitrogen sensitivity as either “high”, “moderate” or “low”, relative to the other embayments based on a statistical classification.

Finally, the nitrogen loading ranks were compared to the nitrogen sensitivity ranks of each embayment within a matrix to identify embayments at greatest risk of eutrophication. The report plots the ranks such that the embayments with the high nitrogen loadings and greatest nitrogen sensitivity lie within the upper left corner of the matrix.

Results

Table E-1 illustrates the relationship between the nitrogen loading rank and embayment sensitivity rank for each embayment. The matrix indicates that the Ipswich River, Weymouth Fore River and Weymouth Back River have the highest potential for eutrophication of the study embayments¹. Additionally, the matrix indicates that Merrimack River, North River (South Shore), Parker River, Sandwich Harbor, Green Harbor River, South River, Gloucester Harbor and Manchester Harbor may also be at some risk of eutrophication.

Note that the results should be interpreted with caution until field work can confirm these embayment classifications (see Recommendations). For example, data collected from the Weymouth Fore River (MWRA, 1995) suggests that this river suffers from poor water quality and high nutrient concentrations, which agrees with our ranking scheme. However, the Weymouth Back River, which also ranked high in this analysis, generally does not exhibit conditions associated with eutrophication.

Conclusions and Recommendations

The results of this study are intended to provide a screening-level assessment of the eutrophication potential of Massachusetts Bays embayments. The results should be used to

¹ Because the embayment ranks are *relative*, they do not necessarily indicate that particular embayments will experience eutrophication. However, the results are useful in prioritizing which embayments may require further study.

Table E-1. Comparison of nitrogen loading and nitrogen sensitivity ranks

Nitrogen sensitivity relative to other study embayments			
← increasing risk of eutrophication →			
	High ⁴	Moderate ⁵	Low ⁶
some potential for eutrophication¹	Ipswich River Weymouth Fore River Weymouth Back River	Merrimack River North River (South) Parker River Sandwich Harbor Green Harbor River South River Gloucester Harbor Manchester Harbor	Lynn Harbor Scorton Harbor Sesuit Harbor North River (North) Rock Harbor
low potential for eutrophication²	Plum Island Sound Danvers River	Beverly Harbor Hingham Bay Plymouth Harbor Saugus River Bass River Rowley River	Cohasset Harbor Hull Bay Pamet River Scituate Harbor Kingston Bay
non-eutrophic³	Weir River Annisquam River Duxbury Bay Wellfleet Harbor	Essex Bay Pines River Barnstable Harbor Salem Harbor Hingham Harbor Eagle Hill River Nahant Bay Provincetown Harbor Marblehead Harbor	Sandy Bay Ipswich Bay

¹Loadings in this range are above the general range of loadings reported for nitrogen limited estuaries that are eutrophic (Jaworski, 1981).

²Loadings in this range are above the "permissible" loading of $54 \text{ kg ha}^{-1} \text{ yr}^{-1}$ estimated by Jaworski (1981), but are below the upper range of loadings ($128 \text{ kg ha}^{-1} \text{ yr}^{-1}$) reported for non-eutrophic estuaries.

³Loadings in this range are below the "permissible" loading of $54 \text{ kg ha}^{-1} \text{ yr}^{-1}$ estimated by Jaworski (1981); empirical data from Jaworski also suggest loadings in this range would not result in eutrophication.

⁴High rank contains values greater than the 75th percentile

⁵Moderate rank contains values between the 25th to 75th percentile

⁶Low rank contains values less than the 25th percentile

identify embayments which may require further evaluation. In addition to the information provided in this study, the authors recommend that MBP:

- Obtain flushing data for the study embayments. Currently, the analysis relies upon a nitrogen sensitivity index to rank embayments. Use of flushing data and mixing characteristics would reduce the uncertainty associated with this assessment. The flushing data should be internally consistent to avoid potential uncertainty associated with different methodologies.
- Conduct a sampling program to verify the results of this study and provide insights into embayment water quality. To conserve resources, MBP could focus the field sampling effort on a subset of study embayments. For a short list of embayments, the authors recommend recording embayment conditions (*e.g.*, presence or absence of eel grass beds, fish kills, etc.) and measuring water quality parameters, such as temperature, dissolved oxygen concentrations, secchi depth, nutrient concentrations, phytoplankton stock and productivity, and chlorophyll-a.
- Contact communities near embayments to discuss local water quality conditions. Such discussions could be useful in identifying particular areas within an embayment that may require further study and management.

1.0 INTRODUCTION

This report provides a screening-level assessment of Massachusetts Bays embayments that may be at risk of eutrophication. The report ranks the study embayments based on their nitrogen loading and potential sensitivity to nutrients. Excessive nitrogen in coastal waters has been implicated as a cause of eutrophication resulting in declining shellfish and finfish productivity, loss of eelgrass beds, and increased algal growth leading to declining species diversity (NRC, 1993). Results of this study will be used by the Massachusetts Bays Program (MBP) to develop appropriate management plans.

The report evaluates a total of forty-four embayments along the North Shore, South Shore and Cape Cod areas (Table 1). Due to the difficulties in accurately delineating heavily urbanized watersheds from topographic maps, the report does not evaluate embayments in the Boston area, including the Charles River, Mystic River, Dorchester Bay, Quincy Bay, Broad Sound and Boston Harbor. The report provides embayment-scale analyses and assumes complete mixing within an embayment. This study is not intended to identify sensitive areas on smaller scales, such as tidal creeks or areas of restricted flow, which could exhibit signs of eutrophication in the absence of embayment-wide eutrophication. Results of this study should therefore not be extrapolated to smaller scales.

Applied Geographics, Inc. (AGI) provided GIS support to Menzie-Cura & Associates, Inc. for this project. AGI produced checkplots, digitized watershed delineations, and incorporated land use data into an ARC/INFO GIS system.

1.1 About the Massachusetts Bays Program

The Massachusetts Bays Program is a cooperative US Environmental Protection Agency and Massachusetts State effort to develop a management plan, known as the "Comprehensive Conservation and Management Plan (CCMP)", for Massachusetts Bays. The CCMP goals are to protect, maintain and, where necessary, restore the Massachusetts Bay and Cape Cod Bay ecosystems. The plan reviews the problems of the Massachusetts Bays, discusses planning efforts in the region, and recommends actions for improved water quality. Work carried out under the MBP is intended to:

- improve the habitats of living resources in Massachusetts Bay;
- protect public health by minimizing risk from environmental contaminants;
- protect and improve water and sediment quality;
- enhance the aesthetic quality of Massachusetts' coast and coastal waters;
- encourage pollution prevention and other environmentally and fiscally sound methods of treatment, clean-up and restoration; and,

- improve access, educational and appropriate recreational opportunities in and around the waters of Massachusetts and Cape Cod Bays.

The MBP has identified as a high priority the need to understand the fate, transport and effects of nutrients from point and non-point sources. This project supports the goals of the CCMP as they relate to the control of nutrients and the eutrophication of Massachusetts coastal waters.

1.2 General approach

To identify the Massachusetts Bays embayments at greatest risk of eutrophication, this study provides a screening-level analysis of nitrogen loading and embayment sensitivity. The approach is consistent with prior evaluations of nutrient loadings and impacts (e.g., Buzzards Bay Project, Cape Cod Commission). The report estimates nitrogen loadings to each embayment originating from wastewater treatment plants and non-point sources (*i.e.*, surface run-off, groundwater, and atmospheric deposition). Non-point source contributions of nitrogen are estimated using a land use analysis similar to Costa (1994) and Valiela *et al.* (in press). This assessment also estimates the ability of an embayment to eliminate nitrogen using the “nitrogen sensitivity index” used by the Cape Cod Commission (CCC) to prioritize embayments in Cape Cod (Eichner, 1995).

To estimate non-point source loadings of nitrogen, a land use analysis was performed for each embayment watershed. The analysis paired land use data within the watershed with nitrogen loading coefficients. Atmospheric nitrogen loads directly onto embayment surfaces were estimated using wet and dry depositional rates from Golomb *et al.* (1996).

To estimate nitrogen loadings from wastewater treatment plants, measured or reported effluent concentrations and flow were used. To ensure that double-counting of nitrogen inputs would not occur, corrections were made to non-point source loading estimates (*i.e.*, those based on land use analysis) to reflect the percentage of homes that are sewered.

Based on the estimates of nitrogen loadings and nitrogen sensitivity, a ranking scheme was developed to evaluate an embayment’s potential for eutrophication relative to the other study embayments. The ranking scheme pairs the physical and hydrologic characteristics of embayments with estimates of nitrogen loadings.

1.3 Limitations and uncertainty of approach

The general approach taken in this study has several limitations:

- The data and methodology will provide a *first-order* approximation of total nitrogen loading. The rankings are intended to be used with other data, such as water quality measurements, presence or absence of eelgrass, and evidence of hypoxia or anoxia, to develop plans or refine rankings. Caveats describing the limitations of the data and results are provided throughout the report.
- Total nitrogen loadings alone do not provide a complete indication of which embayments are at risk of eutrophication. For example, the land use analysis yields *total* nitrogen loadings, and does not differentiate among species (e.g., nitrate, nitrite, ammonium, particulate and dissolved organic nitrogen, etc.). Some nitrogen species are more biologically available than others. In addition, nitrogen loadings may not be useful predictors of eutrophication in coastal systems when other nutrients or conditions are limiting.
- Surface geology influences nitrogen transport. In areas of till and bedrock (such as the North Shore), surface runoff is a significant transport mechanism. In unconsolidated sandy deposits (such as Cape Cod) groundwater dominates nitrogen transport. Therefore, nitrogen loading factors should differ for these regions due to the relative importance of various attenuation processes and loss mechanisms. However, most loading factors available in the literature have been developed for systems dominated by groundwater transport (e.g., Valiela *et al.*, in press; Costa *et al.*, 1994), and for most land uses adequate data do not exist to develop nitrogen loadings factors for surface runoff. The same loadings factors were therefore used for all Massachusetts Bays embayments. This adds a source of uncertainty to estimates of nitrogen loadings, particularly those for embayments in the North and South Shores. Wherever possible, the report estimates the potential range of nitrogen loading coefficients.
- Where groundwater is the dominant transport medium for nitrogen, current land uses may not reflect current nitrogen loadings due to the slow movement of groundwater from inland regions to embayments. Depending upon the groundwater velocity, it may take several years to decades for nitrogen introduced into groundwater to reach an embayment.

2.0 DESCRIPTION OF METHODOLOGY

2.1 Estimates of nitrogen loading

In Massachusetts Bays, point sources of nitrogen are generally limited to wastewater treatment plants and combined sewer overflows. Non-point sources of nitrogen include atmospheric deposition, surface run-off, and groundwater. Surface run-off and groundwater loadings play greater or lesser roles in nitrogen loadings depending upon the local surficial geology. In areas of till and bedrock, such as the North Shore, surface run-off is typically more important than groundwater. In areas of sandy deposits, such as Cape Cod, groundwater is typically more important. In either case, these non-point sources of nitrogen are usually the result of fertilizer application, atmospheric deposition (both onto the watershed and the embayment surface), and septic systems. Less significant sources of nitrogen that are not considered in this report include nitrogen from animal wastes and industrial processes.

In addition to evaluating the loadings to embayments, the report combines the loadings of smaller embayments (subembayments) that contribute to larger systems. For example, the Ipswich River, Parker River and Eagle Hill River embayments were evaluated individually and also as subembayments of the Plum Island Sound embayment (*i.e.*, loadings from the Ipswich River, Parker River and Eagle Hill River embayments were added to those of the Plum Island Sound embayment). This approach allows the watersheds to be evaluated on an individual basis, and as part of a larger-scale analysis.

2.1.1 Atmospheric deposition

To estimate the loadings associated with atmospheric deposition directly onto embayment surfaces, the embayment surface area was multiplied by a nitrogen deposition coefficient ($\text{kg ha}^{-1} \text{ yr}^{-1}$). Coastline information (based on mean high water) used to calculate embayment surface area were obtained from MassGIS, a GIS system developed and maintained by the Massachusetts Executive Office of Environmental Affairs (EOEA). Table 2 summarizes the loading coefficients for atmospheric deposition. The coefficients are based on data from Golomb *et al.* (1996), who summarize wet deposition rates in Massachusetts Bay over a seven year period and estimated dry deposition indirectly using airborne concentrations and depositional velocities.

The study reports low-estimate, best-estimate, and high-estimate depositional rates of 3.7, 5.7 and 12.6 $\text{kg ha}^{-1} \text{ yr}^{-1}$, respectively. This range of coefficients was used to estimate atmospheric loadings directly onto embayment surfaces. The assessment also used these data to estimate atmospheric deposition to embayment watersheds (Section 2.1.2).

2.1.2 Land use

Non-point source loadings of nitrogen were estimated using land use data within an embayment watershed. This analysis was similar to the evaluation completed as part of the Buzzards Bay Project (Costa, 1994). Land use and population data were obtained from MassGIS. MassGIS data were incorporated into an ARC/INFO database and for each land use category, a land use loading coefficient was developed.

2.1.2.1 Watershed delineation

To conduct the land use analysis, the authors delineated the watersheds of the study embayments. Watersheds were delineated using standard hydrographic procedures (see below). For some rivers, the complete watershed was not delineated (discussed in Section 2.1.4). In addition, Massachusetts Bays Program staff requested an analysis of nitrogen loadings using a 1,000 meter coastal boundary. The 1,000 meter boundary was selected as an estimate of the minimum coastal area that contributes nitrogen to an embayment. The report estimates nitrogen loading for both types of delineations.

Delineations from other studies

To conserve resources, MBP and Menzie-Cura & Associates, Inc. agreed to use watershed delineations that were available from other studies. The Cape Cod Commission (CCC) previously delineated watersheds for Cape Cod using composite water table maps for the six Cape Cod groundwater lenses (Eichner *et al.*, 1995). The CCC delineated the watersheds based on groundwater elevation and flow data. These delineations were incorporated into the ARC/INFO database for the Cape Cod embayments of interest.

Delineation of areas with sand deposits

For Cape Cod and the Plymouth/Carver area, where surficial geology consists primarily of unconsolidated sand deposits, the water table topography, rather than surface topography, generally defines the extent of the watersheds. A USGS water table map (1:50,000) was used to delineate the Plymouth/Carver watersheds. This map indicated the direction of groundwater flow as inferred from water table elevations and the location of groundwater divides.

Delineation of areas with till or bedrock

For the remainder of the Massachusetts coast, surface topography was used to delineate watersheds. Wherever possible, standard hydrologic procedures were followed for the delineation of embayment watersheds (*e.g.*, New Hampshire Water Resources Division, 1990).

Surface water flow was assumed to flow perpendicular to contour lines, and topographically flat areas such as swamps were divided equally between bisecting streams.

Checkplot production

Embayment watersheds were delineated on a series of paper checkplots (1:25,000 scale). The checkplots are paper plots of topographic data and other MassGIS data, including:

- coastline
- hydrography
- community boundaries
- USGS major basin boundaries
- USGS sub-basin boundaries
- contours

To facilitate accurate digitization of the watershed delineations, each checkplot contained lines corresponding to USGS quadrangle boundaries. The checkplots also contained the 1,000 meter coastal delineation. The 1,000 meter delineation was computer-generated using the ARC/INFO “buffer” command and the MassGIS 1:25,000 coastline.

Delineation review

After the embayment watersheds were delineated onto the checkplots, they were subject to a two-step review process. Massachusetts Department of Environmental Protection (MADEP) staff conducted an initial technical review of the watershed delineations, followed by a USGS review. The delineations were modified as necessary, based on MADEP and USGS recommendations.

Data processing

Upon final approval by MBP staff, watershed delineations were digitized and stored in an ARC/INFO format.

Quality control/quality assurance

The newly created data sets were checked for the correct ARC/INFO topology. A series of checkplots with the digitized delineations were then produced for each study embayment. These checkplots were compared with the original watershed manuscripts to assure accuracy. Errors were identified and corrected.

2.1.2.2 Land use data

MassGIS contains 21 land use categories. These categories are based on the land uses identified by MacConnell land maps (e.g., MacConnell *et al.*, 1984). To estimate nitrogen loading, the most recent land use data available (in most cases, 1990) was clipped to the watershed boundaries and the highest resolution shoreline data. In cases where 1990 land use data were not available from MassGIS, 1985 land use data was used and such instances were noted in the report tables.

Because a portion of the Merrimack River watershed includes land in New Hampshire, New Hampshire GIS (NHGIS) data was also included in the analysis. However, NHGIS categorizes land use differently than the MassGIS system. To incorporate these data into the analysis, the NHGIS categories were assigned MassGIS categories. Since, in some cases, NHGIS categories are more general than the MassGIS categories, the NHGIS data were divided among several MassGIS categories. For example, it was assumed that the NHGIS urban land use is equal to residential, commercial, industrial, urban open, transportation, and waste disposal MassGIS land uses. These assumptions are summarized below:

NHGIS category	MassGIS categories selected to represent the NHGIS category
active agriculture	cropland and pasture (area divided equally between these categories)
urban	commercial, industrial, urban open, transportation, waste disposal, residential-multifamily, residential - less than 1/4 acre lot, residential - 1/4 to 1/2 acre lot, and residential greater than 1/2 acre lot (area divided equally among these categories)
water	open water
disturbed	mining
wetland	non-forested wetland
cleared and clear-cut	open land
forest	forest

2.1.2.3 Land use loading coefficients

Currently, a variety of nitrogen loading coefficients are available in the published literature (e.g., Frink, 1991; Costa, 1994; Valiela *et al.*, in press). The wide range in magnitude of these coefficients reflects the assumptions and uncertainty associated with their derivation and the types of land uses which they intend to model. To address this uncertainty, a *range* of land use loading coefficients ($\text{kg ha}^{-1} \text{ yr}^{-1}$) were developed for each MassGIS land use category. The coefficients account for various sources of nitrogen, such as septic systems and fertilizer application, and nitrogen losses, such as denitrification. To estimate nitrogen loading rates (e.g., fertilizer application rates, atmospheric deposition, *etc.*), data from Costa (1994), Frimpter *et al.*

(1988), Golomb *et al.* (1996), and Valiela *et al.* (in press) were used. Each nitrogen loading rate was adjusted to account for losses using data reported by Valiela *et al.* (in press). The magnitude of losses varies, depending upon the assumed fate and transport of the nitrogen. For example, nitrogen passing through an aquifer is assumed to be reduced by 35%, while nitrogen passing through both the vadose zone and an aquifer is assumed to be reduced by 75% (Valiela *et al.*, in press). Tables 3 to 7 present the derivation for the loading coefficients. Table 8 summarizes the coefficients.

Note that the land use methodology, while suitable for rural and suburban areas, is less applicable for urbanized zones. As noted by Costa (1994), urban and industrialized areas do not lend themselves to such a loading analysis because wastewater and stormwater are collected in sewer systems and discharged through outfalls. Heavily urbanized areas (*e.g.*, Boston area) were therefore not included in the analysis.

Commercial and Industrial Land Use

Table 3 presents the derivation of the commercial and industrial land use coefficients. These coefficients model atmospheric deposition based on data from Golomb *et al.* (1996). For these values, the report assumes nitrogen losses of 75% associated with the vadose zone and aquifer (Valiela *et al.*, in press). The resulting commercial and industrial coefficients range from 0.9 to 3.2 kg ha⁻¹ yr⁻¹. These coefficients do not account for nitrogen loads from septic sewage. Instead, the residential land use coefficients (see below) account for the annual nitrogen loading generated per capita (This approach does not account for residents that work outside of their own watershed).

Residential Land Use

MassGIS has four categories of residential land use: residential-multifamily, residential-less than 1/4 acre lot, residential-1/4 to 1/2 acre lot, and residential-greater than 1/2 acre lot. Table 4 illustrates the derivation of the nitrogen loading coefficients for each residential category². The coefficients account for the nitrogen loadings due to fertilizer application, atmospheric deposition, and septic sewage. The equation used to calculate residential loading coefficient is:

$$\text{loading coefficient}_{\text{residential}} = \text{atmospheric coefficient} + \text{fertilizer coefficient} + \text{septic system coefficient}$$

² The values in Table 4 are for illustrative purpose only. As discussed later in this section, residential loading coefficients are watershed-specific since they are calculated from the watershed's mean occupancy rate and the percent of homes that are publicly sewered.

Coefficients for atmospheric deposition are based on the data from Golomb *et al.* (1996). These values were adjusted by assuming losses of 90% due to uptake, and losses in the vadose zone and aquifer (Valiela *et al.*, in press).

The equation used to calculate the fertilizer coefficient is:

$$\text{fertilizer coefficient} = \frac{\text{fertilizer application rate} * \text{fertilizer use} * \text{lawn:lot area}}{\text{fraction not lost}}$$

To estimate a range of fertilizer coefficients, fertilizer application rates ($\text{kg ha}^{-1} \text{ yr}^{-1}$) reported by Valiela *et al.* (in press) were used. Additionally, it was assumed that 59% percent of residences use fertilizer³ and that the ratio of lawn area to lot area ranges from 10 to 30%. The analysis also assumes losses of 85% due to gas losses and losses in the vadose zone and groundwater (Valiela *et al.*, in press).

The equation used to calculate the septic system coefficient is:

$$\text{septic system coefficient} = \frac{\text{nitrogen produced per person} * \text{fraction not lost} * \text{watershed-specific occupancy rate} * \text{unit density}}{\text{fraction of residences not publicly sewered}}$$

To estimate the septic system coefficient, data from Valiela *et al.* (in press) and Costa (1994) were used. Valiela *et al.* (in press) estimated nitrogen production ranges from 1.8 to 5.4 $\text{kg person}^{-1} \text{ yr}^{-1}$. They also assumed losses of 74% in septic tanks, leaching fields and groundwater. Because nitrogen loadings associated with septic systems are expressed on a per capita basis, these values were converted to an equivalent loading coefficient ($\text{kg ha}^{-1} \text{ yr}^{-1}$) using occupancy rate (persons unit^{-1}) and unit density (units ha^{-1}) data. Occupancy rates were estimated from US Census Topologically Integrated Geographic Encoding and Referencing (TIGER) files, which provide population and housing unit data. For a given watershed, the occupancy rate is calculated as:

$$\text{occupancy rate} = \text{watershed population} / \text{number of housing units within watershed}$$

Because the TIGER files include data for permanent residents only, the Cape Cod watershed occupancy rates were adjusted to reflect seasonal increases in population. Data from Menzie-Cura & Associates, Inc. (1991) and the Cape Cod Commission (1994) were used to estimate seasonal population increases, which ranged from three-fold to six-fold increases, depending upon the watershed. These increases were assumed to occur three months of the year, and the

³ This an average of reported fertilizer usage by Valiela et al, in press and Costa, 1994.

occupancy rates were adjusted accordingly. For residential-multifamily, residential- less than 1/4 acre, residential- 1/4 to 1/2 acre, and residential- greater than 1/2 acre land uses, unit densities of 12.4, 9.2, 5.0, and 2.5 units ha^{-1} , respectively (Costa *et al.*, 1994) were assumed.

To avoid double-counting of nitrogen inputs, the authors adjusted the septic system coefficient to account for residences known to be sewered. This information was obtained from the US Census Summary Tape File (STF) CD-ROM.

Naturally-vegetated land use

Table 5 illustrates the derivation of the nitrogen loading coefficients for forested, open land, urban open, wetland and salt marsh land uses. These coefficients are based on atmospheric deposition data from Golomb *et al.* (1996). For forest, open land and urban open areas, nitrogen losses of 91% were assumed (Valiela *et al.*, in press). This results in a range of coefficients from 0.3 to 1.1 $\text{kg ha}^{-1} \text{yr}^{-1}$. For wetlands and salt marsh, a range of nitrogen losses of 100% to 14% was assumed, resulting in a range of coefficients from 0 to 10.8 $\text{kg ha}^{-1} \text{yr}^{-1}$.

Recreational land use

Table 6 presents the derivation of the nitrogen loading coefficients for participatory recreation (*e.g.*, golf courses) and spectator recreation (*e.g.*, baseball fields). For these land uses, it was assumed that nitrogen is introduced through fertilizer application and atmospheric deposition. The fertilizer application rates were estimated from data for several Cape Cod golf courses (Cape Cod Commission, 1990). These values were adjusted to account for nitrogen losses of 85% (Valiela *et al.*, in press). Atmospheric deposition were estimated using deposition rates reported by Golomb *et al.* (1996). As with the fertilizer rates, these values were adjusted to account for nitrogen losses. The fertilizer and atmospheric components were summed to estimate the total nitrogen coefficient for recreational land use. These values range from 17.9 to 22.2 $\text{kg ha}^{-1} \text{yr}^{-1}$.

Agricultural land use

Table 7 presents the derivation of the nitrogen loading coefficients for agricultural land uses. There are three MassGIS land use categories associated with agriculture: woody perennial (*e.g.*, cranberry bogs), cropland and pasture. For woody perennial land use, the report uses a range of reported nitrogen application rates for cranberry bogs (Frimpter *et al.*, 1988) and assumes nitrogen losses of 60% (Valiela *et al.*, in press). For cropland and pasture land use, the report assumes a range of nitrogen application rates from Costa (1994) and losses of 85% (Valiela *et al.*, in press). For each type of agricultural land use, this assessment also accounts for atmospheric deposition (Golomb *et al.*, 1996) and losses (Valiela *et al.*, in press). Based on these data, woody perennial, cropland and pasture loading coefficients were estimated to range from 5.4 to 21.0 $\text{kg ha}^{-1} \text{yr}^{-1}$, 11.2 to 21.3 $\text{kg ha}^{-1} \text{yr}^{-1}$, and 5.8 to 11.3 $\text{kg ha}^{-1} \text{yr}^{-1}$, respectively.

2.1.3 Coastal wastewater treatment plants

Wastewater effluent can be a major source of nitrogen to an embayment. To identify those wastewater treatment plants discharging to study embayments, this analysis used the EPA Permit Compliance System (PCS). PCS is a database management system used by EPA to track National Pollutant Discharge Elimination System (NPDES) dischargers nationwide. Among other data, PCS stores each facility's location by street address, town, latitude/longitude coordinates, and USGS basin. Several search queries were developed to identify wastewater treatment plants along the Massachusetts coast. From the search results, outfalls within each embayment watershed delineation were identified.

Nitrogen loadings of many of the wastewater treatment plants were previously estimated in *Sources and Loadings of Pollutants to Massachusetts Bays* (Menzie-Cura & Associates, Inc., 1991). These loadings were estimated from data sources such as NPDES permit applications, Discharge Monitoring Reports, 301(h) studies, Massachusetts Division of Water Pollution Control, and survey reports. Because the report did not provide loading estimates for NPDES minor dischargers, these loadings were estimated by contacting the facilities in question to obtain effluent flow and nitrogen concentration data. If the facility could not supply the relevant information, the facility data was obtained from PCS.

In addition to the facilities identified above, it was estimated that 9% of the effluent from the Nut Island treatment plant mixes into the Weymouth Fore River (Massachusetts Water Resources Authority, 1995). This estimate is based on field studies and computer models by McDowell *et al.* (1991) and Signell (1992).

2.1.4 Rivers

Ingram *et al.* (1994) suggest that only a fraction of the nitrogen input several kilometers upstream of an embayment will reach an embayment. Processes such as uptake, immobilization, sedimentation and denitrification are believed to hinder nitrogen transport over such distances. To prevent gross overestimates of nitrogen loading, MBP staff requested that delineations of river watersheds end at the first upstream dam or impoundment (in the case of the Merrimack River and Weymouth Fore River, the delineation ended at their tidally-influenced reaches). In lieu of modeling various loss mechanisms, upstream nitrogen was estimated by multiplying the river flow at the watershed delineation by nitrogen concentration. This data was obtained from Menzie-Cura & Associates, Inc. (1991) and USGS (1984). To estimate the flow at the upstream reach of a delineation, the flow at a gauging station was adjusted by the flow per unit drainage area ($\text{m}^3 \text{ sec}^{-1} \text{ ha}^{-1}$), where:

$$\text{flow per unit drainage area} = \text{flow at gauging station} / \text{watershed of gauging station}$$

Nitrogen concentrations are not available for some of the study rivers, including the Rowley River, Weymouth Fore River, Weymouth Back River, Weir River, and North River (South Shore). In such cases, a nitrogen concentration of 1.6 mg/L was used, based on the average of reported values for other Massachusetts Rivers (Menzie-Cura & Associates, Inc., 1991).

2.1.5 Off-shore loadings

Oceanic loadings were not quantified in this study. For coastal embayments, exchange with adjacent ocean waters can potentially supply large amounts of nitrogen when tidal inflows are high and/or tidally exchanged waters have high nitrogen concentrations. However, few studies have attempted to quantify tidal contributions due to difficulties in modeling such loadings. In the Recommendations (Section 3.0), the report suggests two approaches which could be implemented to estimate off-shore nitrogen loadings. Both models require data which are not readily available for many Massachusetts embayments, and these data limitations currently prevented even a cursory evaluation of oceanic loadings.

2.2 Statistics on changes in land use

2.2.1 Land use statistics

The report summarizes land use (ha) and land use rates of change (percent) for 1971, 1985 and 1990. For some towns, 1990 land use data is not available from MassGIS. In such cases, the report uses 1985 land use data in lieu of 1990 data. Because New Hampshire GIS does not contain land use data for 1971 and 1985, the report does not evaluate changes in land use for the Merrimack River estuary.

2.2.2 Prediction of changes in land use

This report predicts future changes in land use using the methodology of Costa (1994). This approach provides adequate conservative predictions of growth potential consistent with the goals of this study and the resolution of the available land use data. The methodology assumes that half of the current forested or undeveloped land will be transformed into residential and commercial/industrial land use classes. The report uses the existing ratio between residential and commercial/industrial categories to represent future buildout of forested and undeveloped lands. In addition, it is assumed that new residential development to be proportional to existing land use. This approach provides a simplified approximation of future growth potential. These buildout estimates are used to estimate future nitrogen loadings. Future nitrogen loading estimates do not account for buildout upstream of study delineations.

2.3 Ranking scheme

A ranking scheme was developed to evaluate the sensitivity of the study embayments to eutrophication. The ranking scheme pairs estimates of nitrogen loading with physical characteristics of the embayments.

The Buzzards Bay Project (BBP) has proposed nitrogen loading limits for Buzzards Bay embayments (Buzzards Bay Project, 1994). For embayments whose mean depth is greater than 2 meters, the nitrogen loading limits are expressed as mass per volume per Vollenweider flushing term ($\text{mg m}^{-3} \text{ Vr}^{-1}$). The flushing term is calculated using the hydraulic turnover time of the receiving water (in years). Since such data do not exist for most of the study embayments, the BBP standards could not be utilized in this analysis.

In lieu of a nitrogen evaluation involving flushing rates, the loadings were normalized by embayment surface area ($\text{kg ha}^{-1} \text{ yr}^{-1}$). Jaworski (1981) analyzed the scale of eutrophication of 13 temperate estuaries and freshwater ecosystems and examined the seasonal and long term trends for five estuarine systems in Chesapeake Bay. Jaworski suggested a “permissible” nitrogen loading of $54 \text{ kg ha}^{-1} \text{ yr}^{-1}$ to minimize eutrophication of shallow (4 to 9 meters) nitrogen limited estuarine zones. This value was based on a “permissible” phosphorus loading of $7.5 \text{ kg ha}^{-1} \text{ yr}^{-1}$ and an assumed N/P ratio of 16. We therefore rank study embayments that have loadings below this value as non-eutrophic. Jaworski (1981) also reported the range of nitrogen loadings for estuaries of varying trophic condition. The highest nitrogen loading reported for a nitrogen-limited, non-eutrophic system was $128 \text{ kg ha}^{-1} \text{ yr}^{-1}$ for the Pamlico River estuary. We therefore ranked study embayments that were less than this value, but greater than the “permissible level”, as having a low potential for eutrophication. Study embayments with loadings greater than $128 \text{ kg ha}^{-1} \text{ yr}^{-1}$ were judged to have some potential for eutrophication. These benchmark values are intended to provide a screening-level evaluation of the nitrogen loadings. Exceeding a benchmark value does not necessarily imply eutrophic conditions. Eutrophication potential is also dependent upon whether or not the embayment is nitrogen limited⁴ (not evaluated in this report) and is capable of sufficiently eliminating nitrogen (see below).

⁴ Frequently in marine systems, phytoplankton growth is limited or controlled by the amount of nitrogen available (which is used as a nutrient by the phytoplankton). However, other nutrients, such as phosphorus, or other environmental parameters, such as available light, can also control or limit primary productivity. The ratio of nitrogen to phosphorus as developed by Redfield (1958) is often used to provide insights into which nutrient may limit phytoplankton growth. A nitrogen to phosphorus ratio below 16 is typically interpreted as indicative of nitrogen-limiting conditions.

To judge an embayment's ability to eliminate nitrogen, this assessment uses the "nitrogen sensitivity index", developed by the Cape Cod Commission to prioritize Cape Cod watersheds (Eichner *et al.*, 1995). This scheme evaluates several morphological parameters, including the ratio of the area of the embayment to ocean inlet width, the ratio of the area of the embayment to area of salt water wetlands, and shoreline development. Shoreline development (referred to as "branching" by the CCC) represents the ratio of the length of the shoreline to the circumference of a circle with the area of the embayment⁵. Embayments with shoreline development scores that are significantly greater than one will be more likely to have morphometries that include constricted areas with longer residence times and greater sensitivity to nitrogen loading. An additional CCC parameter, tidal range, was not included in this analysis, since the study embayments' tidal ranges are similar.

A major limitation of the CCC ranking scheme is that it does not incorporate flushing data (currently not available for all of the embayments). The flushing time, the time required for embayment water to exchange with ocean (tidal) water, controls the concentrations and distributions of nutrients in the water, which in turn control the nutrient bioavailability. If nutrients have a relatively short residence time in an embayment, the concentrations that are assimilated by biomass or accumulated by sediments are reduced, and so is the potential for eutrophication. Flushing time invariably affects the loading tolerance of an embayment and thus is a useful parameter in establishing a loading scale.

The CCC scheme assigns a score to each parameter, based on a comparison to benchmark values. Scores are calculated as follows:

score	10	20	30	40	60	80	100
embayment area (ft ²) :	<5,000	5,000 to	10,000	20,000	40,000	80,000	>120,000
ocean inlet width (ft)		9,999	to	to	to	to	
			19,000	39,999	79,999	120,000	
embayment area (ha) :	< 1.0		1.0 to	3.0 to			>7.0
salt water wetlands			2.9	7.0			
area (ha)							
shoreline development	<1.8		1.8 to	2.5 to			>3.0
(unitless)			2.5	3.0			

⁵ The equation to calculate shoreline development is:

$$\text{shoreline development} = \frac{\text{length of embayment shoreline}}{2\sqrt{\pi} \text{ surface area of embayment}}$$

The nitrogen sensitivity index is calculated by adding the parameter scores.

Nitrogen sensitivity is categorized in this report as either “high”, “moderate” or “low”, relative to the other embayments. “High”, “moderate” and “low” ranks correspond to nitrogen sensitivities that are above the 75th percentile, between the 75th and 25th percentiles, or below the 25th percentile, respectively. This classification scheme, otherwise known as quartile comparison, is commonly used in exploratory statistics (Devore and Peck, 1986). This ranking scheme was chosen over a more complex one, given the screening-level approach of the analysis.

Finally, this report compares the nitrogen loading ranks to the nitrogen sensitivity ranks for each embayment. A matrix is constructed of the two ranks to identify embayments at greatest risk of eutrophication. The ranks are plotted such that the embayments with the high nitrogen loadings and greatest nitrogen sensitivity lie within the upper left corner of the matrix. The matrix also identifies systems that have high nitrogen loading but have a low nitrogen sensitivity and vice-versa.

3.0 RESULTS AND RECOMMENDATIONS

3.1 Results

3.1.1 Land use and population data

Appendix A contains the land use data (by year), predicted buildout of land use, and rates of land use change for each embayment. Embayment watersheds that have experienced the greatest increase in residential, commercial and industrial development from 1985 to 1990 include Plum Island Sound, Beverly Harbor, North River (North Shore), North River (South Shore), Kingston Bay, Plymouth Harbor, Barnstable Harbor, Sandwich Harbor, and Wellfleet Harbor. Land use data indicate that cropland and forested areas account for the majority of land that recently has been developed. The analysis predicts large increases in buildout for many of the embayment watersheds in the South Shore, including Cohasset Harbor, South River, North River, Kingston Bay and Plymouth Harbor. The analysis also predicts significant buildout potential for several Cape Cod embayments, including Sandwich Harbor, Scorton Harbor, Barnstable Harbor and Wellfleet Harbor. Of the North Shore embayment watersheds, the analysis predicts large buildouts for the Merrimack River, Plum Island Sound, Ipswich Bay and Beverly Harbor.

Appendix A also contains information on the population, housing units, and sewerage within each delineation. As previously discussed in Section 2.0, the report uses this data to calculate watershed-specific nitrogen loading coefficients for residential land use categories. Embayment watersheds in the North Shore generally have the highest populations and highest percentage of sewered residences. South Shore embayment watersheds follow this trend to a lesser degree. Of the Cape Cod study embayments, only Plymouth Harbor and Green River Harbor River watersheds have high percentages of sewered residences. Year-round populations of embayment watersheds in the Cape Cod area are generally low, compared to other study embayment watersheds.

3.1.2 Nitrogen loading

Tables 9 through 52 summarize the nitrogen loadings for each of the forty-four study embayments. The tables include the estimates for both the 1,000 meter coastal boundary and watershed delineations and for both present and future nitrogen loadings. Future nitrogen loadings are based on the buildout projections. Each table also contains pie charts which summarize the percent contribution of nitrogen from wastewater treatment plants, land use, atmospheric deposition, and river to an embayment. Appendix B contains the data that were used to arrive at the information in the summary tables. Appendix B tables include the area and percent area of each MassGIS land use category, nitrogen loading coefficients and nitrogen loadings by land use.

3.1.2.1 Watershed estimates

Table 53 illustrates the nitrogen loadings expressed as both kg yr^{-1} and $\text{kg ha}^{-1} \text{yr}^{-1}$ for the forty-four study embayments (based on the watershed delineations). The table also indicates which embayments are above and below the benchmark loading levels of 54 and $128 \text{ kg ha}^{-1} \text{yr}^{-1}$. Embayments which exceeded both benchmark loading levels and therefore exhibit some potential for eutrophication include: Scorton Harbor, Merrimack River, Ipswich River, Lynn Harbor, North River (South Shore), Green Harbor River, Weymouth Fore River, Parker River, Sesuit Harbor, Sandwich Harbor, North River (North Shore), Weymouth Back River, Rock Harbor, Manchester Harbor, Gloucester Harbor and South River.

Study embayments at “permissible” levels that are unlikely to result in eutrophication include: Sandy Bay, Pines River, Essex Bay, Barnstable Harbor, Weir River, Annisquam River, Hingham Harbor, Salem Harbor, Ipswich Bay, Eagle Hill River, Duxbury Bay, Wellfleet Harbor, Provincetown Harbor, Marblehead Harbor and Nahant Bay.

3.1.2.2 Comparison of watershed estimates to 1000 m boundary estimates

For most embayments, the 1,000 m boundary nitrogen loading estimates were 2 to 4 times less than their respective watershed loading estimates. These results reflect the fact that the study embayments’ watersheds were generally much larger than the area captured by the 1,000 m boundary. Most of the study embayments that are ranked above the “permissible” level of $54 \text{ kg ha}^{-1} \text{yr}^{-1}$ but below $128 \text{ kg ha}^{-1} \text{yr}^{-1}$ using watershed delineations, would fall within the “permissible” level using 1,000 m boundary delineations. These embayments include the Danvers River, Beverly Harbor, Saugus River, Bass River, Rowley River, Cohasset Harbor, Pamet River, Scituate Harbor, and Kingston Bay. In addition, the North River (North Shore) lies above the $128 \text{ kg ha}^{-1} \text{yr}^{-1}$ benchmark using a watershed delineation, but within the “permissible” level using the 1,000 m boundary delineation. These results highlight the importance of using a reliable watershed delineations for land-use analyses.

3.1.2.3 Comparison of loading estimates to other studies

Only a few studies have previously estimated nitrogen loading to the study embayments. Eichner (1994) estimated nitrogen loadings to Wellfleet Harbor as part of the Wellfleet Harbor Mini-Bays Project (Heufelder, in progress). Using a land use analysis similar to this study, Eichner estimated total nitrogen loadings (adjusted for seasonal fluctuations in populations) of $2.6 \times 10^4 \text{ kg yr}^{-1}$, compared our estimate of $2.8 \times 10^4 \text{ kg yr}^{-1}$. While these estimates agree well with each other, if broken down by source, the loading estimates are significantly different. For example, Eichner estimates that land use and atmospheric contributions are $2.5 \times 10^4 \text{ kg yr}^{-1}$ and

Table 53. Nitrogen loading ranks

	Nitrogen loading ¹ (kg yr ⁻¹)	Surface area (ha)	Nitrogen loading ¹ (kg ha ⁻¹ yr ⁻¹)	Rank
Scorton Harbor	1.4E+04	4.4E-01	3.2E+04	
Merrimack River	1.1E+07	8.9E+02	1.3E+04

¹Values are the average nitrogen loadings for watershed delineations

²Loadings in this range are above the general range of loadings reported for nitrogen limited estuaries that are eutrophic (Jaworski, 1981).

³Loadings in this range are above the "permissible" loading of 54 kg ha⁻¹ yr⁻¹ estimated by Jaworski (1981), but are below the upper range of loadings (128 kg ha⁻¹ yr⁻¹) reported for non-eutrophic estuaries.

⁴Loadings in this range are below the "permissible" loading of 54 kg ha⁻¹ yr⁻¹ estimated by Jaworski (1981); empirical data from Jaworski also suggest loadings in this range would not result in eutrophication.

1.0×10^3 kg yr $^{-1}$, compared to estimates of 1.3×10^4 kg yr $^{-1}$ and 1.4×10^4 kg yr $^{-1}$ by this report. Some of these differences are explained by the selection of input parameters. For example, Eichner assumes an atmospheric depositional rate of 0.2 kg ha $^{-1}$ yr $^{-1}$ for wet deposition. This is over an order of magnitude less than this report's estimated range of 3.7 to 12.6 kg ha $^{-1}$ yr $^{-1}$ (Golomb, 1991). It is likely that the value of 0.2 kg ha $^{-1}$ yr $^{-1}$ underestimates atmospheric deposition since it does not account for dry deposition and may underestimate total annual precipitation. These differences highlight the importance of input parameters and the uncertainty of the methodology.

As part of their *The State of Boston Harbor* report, The Massachusetts Water Resources Authority (MWRA) estimated 3.6×10^5 kg nitrogen yr $^{-1}$ enters the Weymouth Fore and Back Rivers (MWRA, 1995), compared to our estimate of 3.0×10^5 kg yr $^{-1}$. This agreement is not surprising, since this report uses the same assumption regarding Nut Island treatment plant effluent as in the MWRA report and effluent accounts for the majority of the nitrogen entering the system.

3.1.3 Nitrogen sensitivity

Table 54 summarizes the nitrogen sensitivity ranks for the study embayments. The embayments with the highest nitrogen indices (*i.e.*, most sensitive) were Danvers River, Duxbury Bay, Ipswich River, Plum Island Sound, Weir River, Weymouth Fore River, Annisquam River, Wellfleet Harbor and the Weymouth Back River.

3.1.4 Comparison of ranks

Table 55 illustrates the relationship between the nitrogen loading rank and embayment sensitivity rank for each embayment. The matrix indicates that the Ipswich River, Weymouth Fore River and Weymouth Back River have the highest potential for eutrophication of the study embayments⁶. Additionally, the matrix indicates that the Merrimack River, North River (South Shore), Parker River, Sandwich Harbor, Green Harbor River, South River, Gloucester Harbor and Manchester Harbor may also be at some risk of eutrophication. Although the nitrogen loadings for Lynn Harbor, Scorton Harbor, Sesuit Harbor, North River (North Shore) and Rock Harbor also resulted in ranks of “some potential for eutrophication”, these embayments scored low on nitrogen sensitivity. The risk to these embayments is therefore less certain. This report judges the embayments at least risk of eutrophication to be those embayments less than the

⁶ Because the embayment ranks are *relative*, they do not necessarily indicate that particular embayments will experience eutrophication. However, the results are useful in prioritizing which embayments may require further study.

Table 54. Nitrogen sensitivity ranks

	Embayment surface wetlands score	Embayment surface area:saltwater score	Shoreline development	Total score	Rank
Danvers River	40	60	100	200	
Duxbury Bay	40	40	100	180	
Ipswich River	10	60	100	170

¹High rank contains values greater than the 75th percentile

²Moderate rank contains values between the 25th to 75th percentile

³Low rank contains values less than the 25th percentile

Table 55. Comparison of nitrogen loading and nitrogen sensitivity ranks

Nitrogen sensitivity relative to other study embayments			
← increasing risk of eutrophication →			
	High ⁴	Moderate ⁵	Low ⁶
some potential for eutrophication¹	Ipswich River Weymouth Fore River Weymouth Back River	Merrimack River North River (South) Parker River Sandwich Harbor Green Harbor River South River Gloucester Harbor Manchester Harbor	Lynn Harbor Scorton Harbor Sesuit Harbor North River (North) Rock Harbor
low potential for eutrophication²	Plum Island Sound Danvers River	Beverly Harbor Hingham Bay Plymouth Harbor Saugus River Bass River Rowley River	Cohassett Harbor Hull Bay Pamet River Scituate Harbor Kingston Bay
non-eutrophic³	Weir River Annisquam River Duxbury Bay Wellfleet Harbor	Essex Bay Pines River Barnstable Harbor Salem Harbor Hingham Harbor Eagle Hill River Nahant Bay Provincetown Harbor Marblehead Harbor	Sandy Bay Ipswich Bay

¹Loadings in this range are above the general range of loadings reported for nitrogen limited estuaries that are eutrophic (Jaworski, 1981).

²Loadings in this range are above the "permissible" loading of $54 \text{ kg ha}^{-1} \text{ yr}^{-1}$ estimated by Jaworski (1981), but are below the upper range of loadings ($128 \text{ kg ha}^{-1} \text{ yr}^{-1}$) reported for non-eutrophic estuaries.

³Loadings in this range are below the "permissible" loading of $54 \text{ kg ha}^{-1} \text{ yr}^{-1}$ estimated by Jaworski (1981); empirical data from Jaworski also suggest loadings in this range would not result in eutrophication.

⁴High rank contains values greater than the 75th percentile

⁵Moderate rank contains values between the 25th to 75th percentile

⁶Low rank contains values less than the 25th percentile

Jaworski "permissible" loading of 54 kg ha⁻¹ yr⁻¹, regardless of their respective nitrogen sensitivity ranks.

Note that the results should be interpreted with caution until field work can confirm these embayment classifications (see Recommendations). For example, data collected from the Weymouth Fore River (MWRA, 1995) suggests that this river suffers from poor water quality and high nutrient concentrations, which agrees with this report's ranking scheme. However, the Weymouth Back River, which also ranked high in this analysis, generally does not exhibit conditions associated with eutrophication (MWRA, 1995).

3.2 Deliverables

In addition to this report, Menzie-Cura & Associates, Inc. has provided MBP with an electronic copy of all tables and appendices in the form of a Microsoft Excel workbook. The workbook was constructed so that individual input terms (*i.e.*, nitrogen loading coefficients, land use areas, etc.) can easily be adjusted, allowing for the revision of nitrogen loadings estimates as additional information becomes available. The workbook includes the following information:

- land use areas within each watershed;
- land use rates of change within each watershed;
- estimates of populations within each watershed;
- housing and sewerage statistics within each watershed; and,
- nitrogen loading estimates for each watershed.

Menzie-Cura & Associates, Inc. also provided MBP with the delineations and land use data (color plots and ARC/INFO files) for each of the study embayments, which can be obtained by contacting the MBP office at (617) 727-9530 ext. 406.

3.3 Recommendations - *Title*

The results of this study are intended to provide a screening-level assessment of the eutrophication potential of Massachusetts Bays embayments. The results should be used to identify embayments which may require further evaluation. In addition to the information provided in this study, the authors recommend that MBP:

- *✓ Obtain flushing data for the study embayments.* Currently, the report relies upon a nitrogen sensitivity index to rank embayments. The authors recommend the use of flushing data over a sensitivity index. Once such data has been collected, it can be incorporated into a variety of models to estimate trophic condition. For example, Biggs *et al.* (1989) adapted the Vollenweider approach to describe estuarine susceptibility to nutrients and eutrophication. Their approach

involved developing a classification scheme based on physical and hydrologic data and pairing it with watershed classification based on anthropogenic activity and physical characteristics of the watershed.

- ✓ *Conduct a sampling program to verify the results of this study and provide insights into embayment water quality.* To conserve resources, MBP should focus on a subset of the study embayments. This subset should include embayments representative of each nitrogen loading rank to substantiate the findings of this report. A recommended short list includes:

Short list of study embayments for field verification

Some potential for eutrophication:

Ipswich River, Gloucester Harbor, Sesuit Harbor, Lynn Harbor, South River

Low potential for eutrophication:

Danvers River, Plymouth Harbor, Scituate Harbor

Eutrophication unlikely:

Weir River, Salem Harbor, Sandy Bay

These embayments represent a wide-range of land uses, surficial geologies and population sizes.

For such a short list, the authors recommend recording embayment conditions and measuring water quality parameters. Indicators of eutrophication include presence or absence of eelgrass, hypoxic or anoxic conditions, sediment organic content and macroalgae blooms. Water quality parameters which could be measured include temperature, dissolved oxygen levels, secchi depth, nutrient concentrations (e.g., nitrate, nitrite, total kjeldahl nitrogen, total phosphorus), phytoplankton stock and productivity, and chlorophyll-a. Results of field verification may also provide a better understanding of the uncertainty associated with land-use analyses.

- ✓ *Contact communities near embayments to discuss local water quality conditions.* Such discussions could be useful in identifying particular areas within an embayment that may require further study and management.

- ✓ *Develop nitrogen loading coefficients for surface runoff.* If future nitrogen loading estimates are undertaken, the authors recommend developing nitrogen loading coefficients for areas whose nitrogen transport is primarily controlled by surface runoff (i.e., the North Shore). Because the nitrogen loading coefficients play a significant role in a land-use analysis, surface runoff coefficients for the North Shore will likely provide some refinement on the estimates provided in this report.

5 ✓ Obtain the necessary data to estimate off-shore contributions of nitrogen. For coastal embayments, exchange with adjacent ocean waters can potentially supply large amounts of nitrogen. Tidal contributions of nitrogen can be significant when tidal inflows are high and/or tidally exchanged waters have high nitrogen concentrations. However, few studies have attempted to quantify tidal contributions due to difficulties in modeling such loadings. Oceanic nitrogen loadings may not represent available nitrogen in coastal systems because nitrogen in ocean waters will enter coastal embayments at depth due the presence of a pycnocline. If the bay or estuary is not well-mixed, this nitrogen may remain at depths below the photic zone and thus may not enhance algae growth. In addition, a significant fraction of the nitrogen that enters coastal embayments on the ingoing tides may be the same nitrogen that has previously left the embayment on the outgoing tides. Tidal inputs may thus be offset by tidal losses, and in some cases oceanic loadings may not represent available nitrogen in coastal systems. In other areas, such as upwelling areas, off-shore inputs may be very important.

A variety of physically-based exchange models can be used to estimate hydraulic loadings to coastal embayments, such as harbors and estuaries. The authors discuss two such approaches, the tidal prism model and the salinity balance model, below. Both models require data which are not readily available for many Massachusetts embayments, and these data limitations prevented even a cursory evaluation of oceanic loadings. Both models can only provide a first-order approximation of offshore loadings because coastal systems are highly dynamic in nature and may not be adequately represented by simple models incorporating limited data sets.

Tidal Prism Model

This model assumes that the volumetric in-flow of tidal waters can be computed based on the geometry of a coastal embayment and the tidal height of the embayment. The volumetric in-flow can then be multiplied by the annual average concentration of nitrogen at the open-ocean boundary to determine the annual oceanic nitrogen loading to an embayment of interest. The informational requirements of this approach thus include: tidal heights of coastal embayments, geometry of embayments (e.g., surface area and average depth), and the average concentration of total nitrogen (TN) at the open-ocean boundary.

For an embayment, the following formula could be used to determine the annual off-shore nitrogen loading:

$$\begin{aligned} \text{Annual N loading of tidal inflow} &= \text{tidal prism volume} * \text{annual average TN concentration} \\ &\quad * 2 \text{ tides/day} * 365 \text{ days/year} \end{aligned}$$

where, tidal prism volume = embayment surface area * tidal height

Extensive monitoring data are necessary to obtain a useful average annual TN concentration. TN concentrations are seasonally-dependent, and monthly monitoring data should be used to calculate a representative average. The authors recommend that parties interested in such data collection should review the monitoring plan developed and implemented as part of the Wellfleet Harbor Mini-Bays Project.

Salinity Balance Model

This model assumes that the volumetric in-flow of tidal waters can be estimated by constructing a salinity balance for a coastal embayment and requires: annual average freshwater volumetric flow, annual average salinity at the open-ocean boundary, annual average salinity inside the embayment, and the annual average concentration of total nitrogen (TN) at the open-ocean boundary.

The volumetric in-flow of tidal waters (T_i) is calculated in the following manner:

$$T_i = [S_o / (S_i - S_o)] * R$$

where, S_i = annual average salinity at the open-ocean boundary;

S_o = annual average salinity inside the embayment; and

R = annual average volumetric inflow of freshwater into the embayment.

The volumetric in-flow of tidal waters can then be multiplied by the annual average concentration of nitrogen at the open-ocean boundary to determine the annual oceanic nitrogen loading to an embayment of interest. Extensive monitoring data are necessary to obtain useful annual average TN concentrations and annual average salinities.

The annual average volumetric inflow of freshwater into an embayment can be estimated by using annual river flows for embayments served by major river systems. For embayments not served by major river systems, annual average freshwater flows can be estimated by multiplying annual average precipitation rates for the embayment watershed by appropriate runoff or recharge coefficients. For embayment watersheds having predominantly bedrock geologies (*i.e.*, embayments on the North and South Shores), a runoff coefficient of 0.35 may be appropriate. This coefficient was proposed by Nationwide Urban Runoff Program (NURP) and is an average for residential, commercial, and open land uses (USEPA, 1983). For embayment watersheds where sand and till materials predominate and groundwater is the principal transport medium for freshwater into coastal embayments (*i.e.*, Cape Cod), an annual recharge rate of 16 inches per year may be appropriate. This value is an assumed value for groundwater lenses of Cape Cod (Ed Eichner, Cape Cod Commission, personal communication).

Table 8. Summary of nitrogen loading coefficients

MassGIS code	MassGIS category	Description	Nitrogen loading coefficient (kg ha ⁻¹ y ⁻¹)		
			low	mean	high
C1	Cropland	intensive agriculture (e.g., corn)	11.2	16.0	21.3
C2	Pasture	extensive agriculture (e.g., hay, dairy)	5.8	8.3	11.3
C3	Forest	forest	0.3	0.5	1.1
C4	Wetland	non-forested freshwater wetland	0.0	1.3	10.8
C5	Mining	sand, gravel and rock pits	0.9	1.4	3.2
C6	Open land	abandoned agriculture, power lines, areas of no vegetation	0.3	0.5	1.1
C7	Participatory recreation	golf courses, tennis, playgrounds, skiing	17.9	19.3	22.2
C8	Spectator recreation	stadiums, racetracks, fairgrounds, drive-ins	17.9	19.3	22.2
C9	Water-based recreation	beaches, marinas, swimming pools	3.7	5.7	12.6
C10	Residential ^a	multi-family	18.0	48.6	57.5
C11	Residential ^a	< ¼ acre lots	13.5	36.7	44.1
C12	Residential ^a	¼ to ½ acre lots	7.7	21.1	26.5
C13	Residential ^a	> ½ acre lots	4.2	11.9	16.2
C14	Salt marsh	salt marsh	0.0	1.3	10.8
C15	Commercial	general urban, shopping centers	0.9	1.4	3.2
C16	Industrial	light and heavy industry	0.9	1.4	3.2
C17	Urban open	parks, cemeteries, public and institutional greenspace	0.3	0.5	1.1
C18	Transportation	airports, docks, divided highways	0.9	1.4	3.2
C19	Waste disposal	landfills, sewage lagoons	0.9	1.4	3.2
C20	Open water	freshwater ponds and rivers	0.0	2.5	10.8
C21	Woody perennial	cranberry bogs, orchards	5.4	14.8	21.0
	Embayment surface	atmospheric deposition	3.7	5.7	12.6

^aThe residential loading coefficients used in the analysis vary based upon the watershed's occupancy rate.
The values presented in this table reflect an occupancy rate of 3 persons unit⁻¹.

Marblehead Harbor	1.3E+03	1.4E+02	8.8E+00	
Nahant Bay	9.9E+03	1.3E+03	7.5E+00	

¹Values are the average nitrogen loadings for watershed delineations

²Loadings in this range are above the general range of loadings reported for nitrogen limited estuaries that are eutrophic (Jaworski, 1981).

³Loadings in this range are above the "permissible" loading of 54 kg ha⁻¹ yr⁻¹ estimated by Jaworski (1981), but are below the upper range of loadings (128 kg ha⁻¹ yr⁻¹) reported for non-eutrophic estuaries.

⁴Loadings in this range are below the "permissible" loading of 54 kg ha⁻¹ yr⁻¹ estimated by Jaworski (1981); empirical data from Jaworski also suggest loadings in this range would not result in eutrophication.

Table 54. Nitrogen sensitivity ranks

	Embayment surface area:saltwater wetlands score	Embayment surface area:inlet width score	Shoreline development	Total score	Rank
Danvers River	40	60	100	200	
Duxbury Bay	40	40	100	180	
Ipswich River	10	60	100	170	
Plum Island Sound	10	60	100	170
